

Application Note AN3201-02: Pitch Shifting by Frank Thomson

Introduction

This application note describes a basic pitch shifting routine that can be implemented in the DRE. The DRE is capable of performing pitch shifting by either reading faster (pitch up) or slower (pitch down) through the stored samples. This is accomplished by running the samples through a circular buffer and using two pointers to read from the circular buffer. The two pointers are 180° apart in the circular buffer so that as one pointer is crossing from the end to the start of the buffer, the other pointer is mid-way through the buffer. This is done with two sawtooth waveforms, the discontinuity being where the end-to-start crossing occurs for the pointer.

A sample is calculated by first linearly interpolating between the samples at one pointer, then at the other pointer, then crossfading between the 2 pointers such that the crossfade coefficient is 0 for the pointer as it crosses from the end to the start of the circular buffer. The coefficient is calculated by the digital LFOs along with the sawtooths required to generate the two pointers.

<u>Algorithm</u>

The digital LFOs are calculated using 24-bit math in the chorus generator block of the DRE. The 20 MSBs (Most Significant Bits) of the results are fed out for use by the address generator and the MAC. Of these 20 bits, the 13 MSBs are routed to the address generator and the 7 LSBs (Least Significant Bits) are used as the interpolation coefficient for the MAC.

The 13 bits routed to the address generator are in two's complement format, giving an effective range of +4095 to -4096. This range is controlled by the amplitude coefficient for the LFO which is 15 bits and always less than 1.

The frequency is controlled by a 13 bit coefficient. These 13 bits are the LSBs of an 18 bit word used internal to the digital LFOs.

The sawtooth waveform frequency is calculated by (assuming a 12.288MHz crystal is being used which results in a 48kHz sample rate):

 $f = (F^*Fs^*C)/(2^*M^*H) = 0.045777^*F$

where F = 13 bit frequency coefficient Fs = 48000 (sample rate) C = 4194304 (0x400000, a constant used internally in the LFO) M = 262143 (0x3FFFF, internal maximum 18-bit value) H = 8388607 (0x7FFFFF, maximum positive 24-bit value)

For a frequency coefficient F of 1, K = 1/262143 and results in f = 0.04577Hz. For a frequency coefficient of 8191 (the maximum 13 bit value), K = 8191/262143 and results in f = 374.9557Hz.

Pitch Up

Calculating the proper frequency and amplitude coefficient for pitch shifting is a dependent on both length of the circular buffer and the amount of pitch shift desired. We select the buffer to be 8192 samples long (maximum amplitude of the sawtooth waveform) which results in an amplitude coefficient of 32767 (maximum 15 bit amplitude coefficient).

To determine the frequency coefficient, we first need to determine the amount of shift desired. For the case of pitching up 1 octave, we want to play the 8192 samples from the circular buffer at an effective rate of double the sample rate. An easy way to calculate this is to determine how much faster we want to play the samples than the base sample rate. In this case, we want to play the 8192 samples at a rate that is effectively 48kHz added the base sample rate of 48kHz. Since the samples are written to the circular buffer using addresses generated by a down counter, and as the sawtooth is generated by an up counter, we need to invert the sawtooth waveform for the pitch up case. This is done by using the COMPA flag in a CHR instruction. Therefore, to calculate the frequency coefficient, start by finding the sawtooth frequency needed:

f = 48kHz faster / 8192 samples = 5.85938Hz

From $f = (F^*Fs^*C)/(2^*M^*SIN)$ above, we can rearrange the equation to solve for F:

F = (2*M*H*f)/(Fs*C) = 127.999, quantized to 128.

To shift up by amount n, where n is the fraction of an octave, the aggregate formula is:

 $F = [2*M*H*(2^{n} - 1)]/(C*BufferSize) = 1048571.185*(2^{n} - 1)/BufferSize)$

Thus shifting up by 1/2 an octave, using the same 8192 buffer size, gives:

 $F = 1048571.185*(2^{1/2} - 1)/8192 = 53.019$, quantized to 53.

Shifting up by 5 semitones gives:

 $F = 1048571.185*(2^{5/12} - 1)/8192 = 42.859$, quantized to 43.

Shifting up by 40 cents gives:

 $F = 1048571.185*(2^{0.40/12} - 1)/8192 = 2.992$, quantized to 3.

Pitch Down

Pitching down is similar to pitching up, except that rather than adding to the base sample rate, we are subtracting from it. In this case, we do not invert the sawtooth waveform. As an example, if we wished to pitch down by 1 octave, we effectively want to subtract 24kHz from the sample rate. Using the same 8192 sample buffer, we calculate as follows:

f = 24kHz slower / 8192 samples = 2.92969Hz

F = (2*M*H*f)/(Fs*C) = 63.9997, guantized to 64.

To shift down by amount n, where n is the fraction of an octave, the aggregate formula is:

 $F = [2*M*H*(1 - 2^{-n})]/(C*BufferSize) = 1048571.185*(1 - 2^{-n})/BufferSize$

Thus shifting down by 1/2 an octave, using the same 8192 buffer size, gives:

 $F = 1048571.185*(1 - 2^{-1/2})/8192 = 37.490$, quantized to 37.

Shifting down by 5 semitones gives:

 $F = 1048571.185*(1 - 2^{-5/12})/8192 = 32.108$, quantized to 32.

Shifting down by 40 cents gives:

 $F = 1048571.185*(1 - 2^{-0.40/12})/8192 = 2.923$, guantized to 3.
