Low Distortion, Wide Bandwidth Voltage Feedback Clamp Amps

AD8036/AD8037

FEATURES

Superb Clamping Characteristics
- **3 mV Clamp Error**
- **1.5 ns Overdrive Recovery**
- **Minimized Nonlinear Clamping Region**
- **240 MHz Clamp Input Bandwidth**
- **±3.9 V Clamp Input Range**

Wide Bandwidth	**AD8036**	**AD8037**
Small Signal	**240 MHz**	**270 MHz**
Large Signal (4 V p-p)	**195 MHz**	**190 MHz**

Good DC Characteristics
- **2 mV Offset**
- **10 μV/°C Drift**

Ultralow Distortion, Low Noise
- **–72 dBc typ @ 20 MHz**
- **4.5 nV/√Hz Input Voltage Noise**

High Speed
- **Slew Rate 1500 V/μs**
- **Settling 10 ns to 0.1%, 16 ns to 0.01%**

±3 V to ±5 V Supply Operation

APPLICATIONS
- **ADC Buffer**
- **IF/RF Signal Processing**
- **High Quality Imaging**
- **Broadcast Video Systems**
- **Video Amplifier**
- **Full Wave Rectifier**

PRODUCT DESCRIPTION

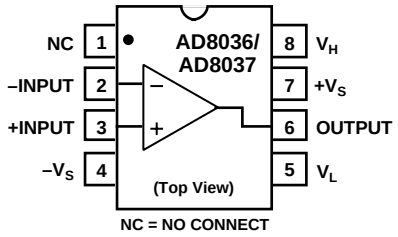
The AD8036 and AD8037 are wide bandwidth, low distortion clamping amplifiers. The AD8036 is unity gain stable. The AD8037 is stable at a gain of two or greater. These devices allow the designer to specify a high (V_{CH}) and low (V_{CL}) output clamp voltage. The output signal will clamp at these specified levels. Utilizing a unique patent pending CLAMPIN™ input clamp architecture, the AD8036 and AD8037 offer a 10× improvement in clamp performance compared to traditional output clamping devices. In particular, clamp error is typically 3 mV or less and distortion in the clamp region is minimized. This product can be used as a classical op amp or a clamp amplifier where a high and low output voltage are specified.

The AD8036 and AD8037, which utilize a voltage feedback architecture, meet the requirements of many applications which previously depended on current feedback amplifiers. The AD8036 and AD8037 exhibit an exceptionally fast and accurate pulse response (16 ns to 0.01%), extremely wide small-signal and large-signal bandwidths and ultralow distortion. The AD8036 achieves –66 dBc at 20 MHz, and 240 MHz small-signal and 195 MHz large-signal bandwidths. The AD8036 and AD8037's recover from 2× clamp overdrive within 1.5 ns. These characteristics position the AD8036/AD8037 ideally for driving as well as buffering flash and high resolution ADCs.

CLAMPIN is a trademark of Analog Devices, Inc.

FUNCTIONAL BLOCK DIAGRAM

8-Lead Plastic DIP (N), Cerdip (Q), and SO Packages



In addition to traditional output clamp amplifier applications, the input clamp architecture supports the clamp levels as additional inputs to the amplifier. As such, in addition to static dc clamp levels, signals with speeds up to 240 MHz can be applied to the clamp pins. The clamp values can also be set to any value within the output voltage range provided that V_H is greater that V_L. Due to these clamp characteristics, the AD8036 and AD8037 can be used in nontraditional applications such as a full-wave rectifier, a pulse generator, or an amplitude modulator. These novel applications are only examples of some of the diverse applications which can be designed with input clamps.

The AD8036 is offered in chips, industrial (–40°C to +85°C) and military (–55°C to +125°C) package temperature ranges and the AD8037 in industrial. Industrial versions are available in plastic DIP and SOIC; MIL versions are packaged in cerdip.

NOTES

[1]Stresses above those listed under Absolute Maximum Ratings may cause permanent damage to the device. This is a stress rating only; functional operation of the device at these or any other conditions above those indicated in the operational section of this specification is not implied. Exposure to absolute maximum rating conditions for extended periods may affect device reliability.

[2]Specification is for device in free air:
8-Lead Plastic DIP: θ_{JA} = 90°C/W
8-Lead SOIC: θ_{JA} = 155°C/W
8-Lead Cerdip: θ_{JA} = 110°C/W.

MAXIMUM POWER DISSIPATION

The maximum power that can be safely dissipated by these devices is limited by the associated rise in junction temperature. The maximum safe junction temperature for plastic encapsulated devices is determined by the glass transition temperature of the plastic, approximately +150°C. Exceeding this limit temporarily may cause a shift in parametric performance due to a change in the stresses exerted on the die by the package. Exceeding a junction temperature of +175°C for an extended period can result in device failure.

While the AD8036 and AD8037 are internally short circuit protected, this may not be sufficient to guarantee that the maximum junction temperature (+150°C) is not exceeded under all conditions. To ensure proper operation, it is necessary to observe the maximum power derating curves.

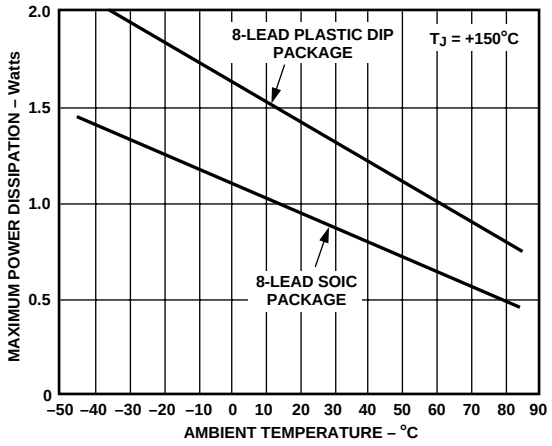

Figure 2. Plot of Maximum Power Dissipation vs. Temperature

ORDERING GUIDE

Model	Temperature Range	Package Description	Package Option
AD8036AN	–40°C to +85°C	Plastic DIP	N-8

CAUTION

ESD (electrostatic discharge) sensitive device. Electrostatic charges as high as 4000 V readily accumulate on the human body and test equipment and can discharge without detection. Although these devices feature proprietary ESD protection circuitry, permanent damage may occur on devices subjected to high energy electrostatic discharges. Therefore, proper ESD precautions are recommended to avoid performance degradation or loss of functionality.

THEORY OF OPERATION

General

The AD8036 and AD8037 are wide bandwidth, voltage feedback clamp amplifiers. Since their open-loop frequency response follows the conventional 6 dB/octave roll-off, their gain bandwidth product is basically constant. Increasing their closed-loop gain results in a corresponding decrease in small signal bandwidth. This can be observed by noting the bandwidth specification, between the AD8036 (gain of 1) and AD8037 (gain of 2). The AD8036/AD8037 typically maintain 65 degrees of phase margin. This high margin minimizes the effects of signal and noise peaking.

While the AD8036 and AD8037 can be used in either an inverting or noninverting configuration, the clamp function will only work in the noninverting mode. As such, this section shows connections only in the noninverting configuration. Applications that require an inverting configuration will be discussed in the Applications section. In applications that do not require clamping, Pins 5 and 8 (respectively V_L and V_H) may be left floating. See Input Clamp Amp Operation and Applications sections otherwise.

Feedback Resistor Choice

The value of the feedback resistor is critical for optimum performance on the AD8036 (gain +1) and less critical as the gain increases. Therefore, this section is specifically targeted at the AD8036.

At minimum stable gain (+1), the AD8036 provides optimum dynamic performance with R_F = 140 Ω. This resistor acts only as a parasitic suppressor against damped RF oscillations that can occur due to lead (input, feedback) inductance and parasitic capacitance. This value of R_F provides the best combination of wide bandwidth, low parasitic peaking, and fast settling time.

In fact, for the same reasons, a 100–130 Ω resistor should be placed in series with the positive input for other AD8036 noninverting configurations. The correct connection is shown in Figure 69.

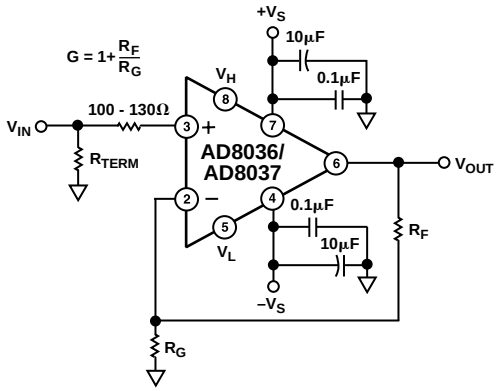

Figure 69. Noninverting Operation

For general voltage gain applications, the amplifier bandwidth can be closely estimated as:

$$f_{3\,dB} \cong \frac{\omega_O}{2\pi\left[1+\left(\frac{R_F}{R_G}\right)\right]}$$

This estimation loses accuracy for gains of +2/–1 or lower due to the amplifier's damping factor. For these "low gain" cases, the bandwidth will actually extend beyond the calculated value (see Closed-Loop BW plots, Figures 15 and 27).

Pulse Response

Unlike a traditional voltage feedback amplifier, where the slew speed is dictated by its front end dc quiescent current and gain bandwidth product, the AD8036 and AD8037 provide "on demand" current that increases proportionally to the input "step" signal amplitude. This results in slew rates (1200 V/µs) comparable to wideband current feedback designs. This, combined with relatively low input noise current (2.1 pA/$\sqrt{\text{Hz}}$), gives the AD8036 and AD8037 the best attributes of both voltage and current feedback amplifiers.

Large Signal Performance

The outstanding large signal operation of the AD8036 and AD8037 is due to a unique, proprietary design architecture. In order to maintain this level of performance, the maximum 350 V-MHz product must be observed, (e.g., @ 100 MHz, $V_O \le 3.5$ V p-p).

Power Supply and Input Clamp Bypassing

Adequate power supply bypassing can be critical when optimizing the performance of a high frequency circuit. Inductance in the power supply leads can form resonant circuits that produce peaking in the amplifier's response. In addition, if large current transients must be delivered to the load, then bypass capacitors (typically greater than 1 µF) will be required to provide the best settling time and lowest distortion. A parallel combination of at least 4.7 µF, and between 0.1 µF and 0.01 µF, is recommended. Some brands of electrolytic capacitors will require a small series damping resistor ≈4.7 Ω for optimum results.

When the AD8036 and AD8037 are used in clamping mode, and a dc voltage is connected to clamp inputs V_H and V_L, a 0.1 µF bypassing capacitor is required between each input pin and ground in order to maintain stability.

Driving Capacitive Loads

The AD8036 and AD8037 were designed primarily to drive nonreactive loads. If driving loads with a capacitive component is desired, the best frequency response is obtained by the addition of a small series resistance as shown in Figure 70. The accompanying graph shows the optimum value for R_{SERIES} vs. capacitive load. It is worth noting that the frequency response of the circuit when driving large capacitive loads will be dominated by the passive roll-off of R_{SERIES} and C_L. For capacitive loads of 6 pF or less, no R_{SERIES} is necessary.

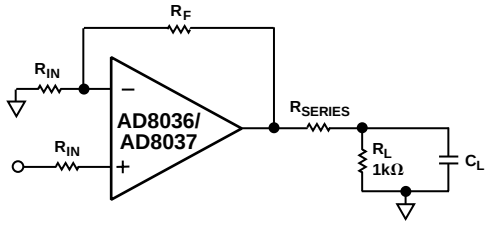

Figure 70. Driving Capacitive Loads

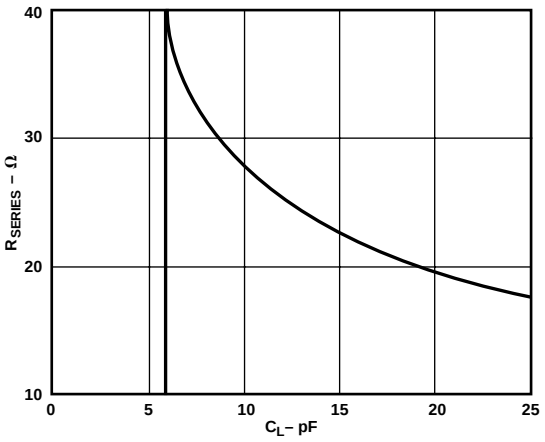

Figure 71. Recommended R_{SERIES} vs. Capacitive Load

INPUT CLAMPING AMPLIFIER OPERATION

The key to the AD8036 and AD8037's fast, accurate clamp and amplifier performance is their unique patent pending CLAMPIN input clamp architecture. This new design reduces clamp errors by more than 10× over previous output clamp based circuits, as well as substantially increasing the bandwidth, precision and versatility of the clamp inputs.

Figure 72 is an idealized block diagram of the AD8036 connected as a unity gain voltage follower. The primary signal path comprises A1 (a 1200 V/µs, 240 MHz high voltage gain, differential to single-ended amplifier) and A2 (a G = +1 high current gain output buffer). The AD8037 differs from the AD8036 only in that A1 is optimized for closed-loop gains of two or greater.

The CLAMPIN section is comprised of comparators C_H and C_L, which drive switch S1 through a decoder. The unity-gain buffers in series with $+V_{IN}$, V_H, and V_L inputs isolate the input pins from the comparators and S1 without reducing bandwidth or precision.

The two comparators have about the same bandwidth as A1 (240 MHz), so they can keep up with signals within the useful bandwidth of the AD8036. To illustrate the operation of the CLAMPIN circuit, consider the case where V_H is referenced to +1 V, V_L is open, and the AD8036 is set for a gain of +1, by connecting its output back to its inverting input through the recommended 140 Ω feedback resistor. Note that the main signal path always operates closed loop, since the CLAMPIN circuit only affects A1's noninverting input.

If a 0 V to +2 V voltage ramp is applied to the AD8036's $+V_{IN}$ for the connection just described, V_{OUT} should track $+V_{IN}$ perfectly up to +1 V, then should limit at exactly +1 V as $+V_{IN}$ continues to +2 V.

In practice, the AD8036 comes close to this ideal behavior. As the $+V_{IN}$ input voltage ramps from zero to 1 V, the output of the high limit comparator C_H starts in the off state, as does the output of C_L. When $+V_{IN}$ just exceeds V_{IN} (ideally, by say 1 µV, practically by about 18 mV), C_H changes state, switching S1 from "A" to "B" reference level. Since the + input of A1 is now connected to V_H, further increases in $+V_{IN}$ have no effect on the AD8036's output voltage. In short, the AD8036 is now operating as a unity-gain buffer for the V_H input, as any variation in V_H, for V_H > 1 V, will be faithfully reproduced at V_{OUT}.

Operation of the AD8036 for negative input voltages and negative clamp levels on V_L is similar, with comparator C_L controlling S1. Since the comparators see the voltage on the $+V_{IN}$ pin as their common reference level, then the voltage V_H and V_L are defined as "High" or "Low" with respect to $+V_{IN}$. For example, if V_{IN} is set to zero volts, V_H is open, and V_L is +1 V, comparator C_L will switch S1 to "C," so the AD8036 will buffer the voltage on V_L and ignore $+V_{IN}$.

The performance of the AD8036 and AD8037 closely matches the ideal just described. The comparator's threshold extends from 60 mV inside the clamp window defined by the voltages on V_L and V_H to 60 mV beyond the window's edge. Switch S1 is implemented with current steering, so that A1's +input makes a continuous transition from say, V_{IN} to V_H as the input voltage traverses the comparator's input threshold from 0.9 V to 1.0 V for V_H = 1.0 V.

The practical effect of these nonidealities is to soften the transition from amplification to clamping modes, without compromising the absolute clamp limit set by the CLAMPIN circuit. Figure 73 is a graph of V_{OUT} vs. V_{IN} for the AD8036 and a typical output clamp amplifier. Both amplifiers are set for G = +1 and V_H = +1 V.

The worst case error between V_{OUT} (ideally clamped) and V_{OUT} (actual) is typically 18 mV times the amplifier closed-loop gain. This occurs when V_{IN} equals V_H (or V_L). As V_{IN} goes above and/or below this limit, V_{OUT} will settle to within 5 mV of the ideal value.

In contrast, the output clamp amplifier's transfer curve typically will show some compression starting at an input of 0.8 V, and can have an output voltage as far as 200 mV over the clamp limit. In addition, since the output clamp in effect causes the amplifier to operate open loop in clamp mode, the amplifier's output impedance will increase, potentially causing additional errors.

The AD8036's and AD8037's CLAMPIN input clamp architecture works only for noninverting or follower applications and, since it operates on the input, the clamp voltage levels V_H and V_L, and input error limits will be multiplied by the amplifier's

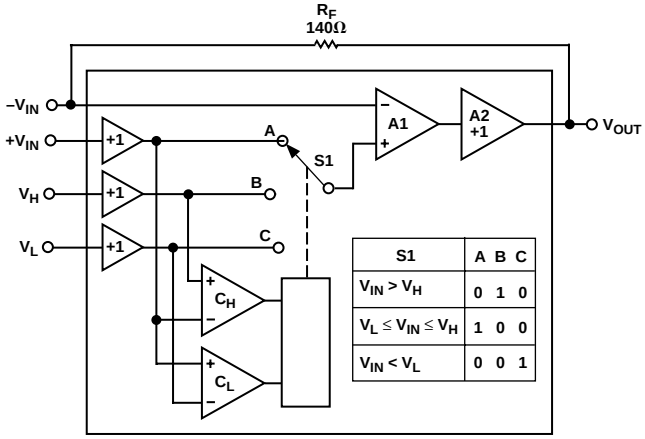

Figure 72. AD8036/AD8037 Clamp Amp System

closed-loop gain at the output. For instance, to set an output limit of ±1 V for an AD8037 operating at a gain of 3.0, V_H and V_L would need to be set to +0.333 V and –0.333 V, respectively.

The only restriction on using the AD8036's and AD8037's $+V_{IN}$, V_L, V_H pins as inputs is that the maximum voltage difference between $+V_{IN}$ and V_H or V_L should not exceed 6.3 V, and all three voltages be within the supply voltage range. For example, if V_L is set at –3 V, then V_{IN} should not exceed +3.3 V.

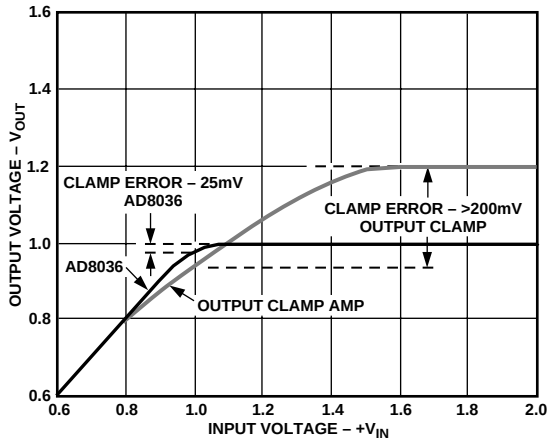

Figure 73. Output Clamp Error vs. Input Clamp Error

AD8036/AD8037 APPLICATIONS

The AD8036 and AD8037 use a unique input clamping circuit to perform the clamping function. As a result, they provide the clamping function better than traditional output clamping devices and provide additional flexibility to perform other unique applications.

There are, however, some restrictions on circuit configurations; and some calculations need to be performed in order to figure the clamping level, as a result of clamping being performed at the input stage.

The major restriction on the clamping feature of the AD8036/AD8037 is that clamping occurs only when using the amplifiers in the noninverting mode. To clamp in an inverting circuit, an additional inverting gain stage is required. Another restriction is that V_H be greater than V_L, and that each be within the output voltage range of the amplifier (±3.9 V). V_H can go below ground and V_L can go above ground as long as V_H is kept higher than V_L.

Unity Gain Clamping

The simplest circuit for calculating the clamp levels is a unity gain follower as shown in Figure 74. In this case, the AD8036 should be used since it is compensated for noninverting unity gain.

This circuit will clamp at an upper voltage set by V_H (the voltage applied to Pin 8) and a lower voltage set by V_L (the voltage applied to Pin 5).

Clamping with Gain

Figure 75 shows an AD8037 configured for a noninverting gain of two. The AD8037 is used in this circuit since it is compensated for gains of two or greater and provides greater bandwidth. In this case, the high clamping level at the output will

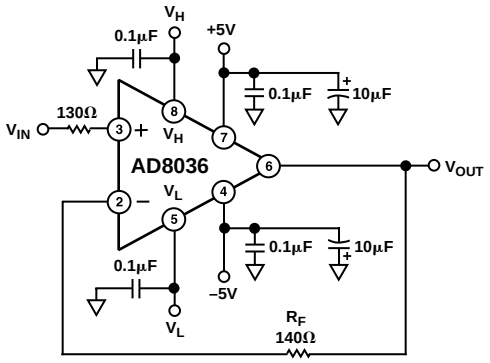

Figure 74. Unity Gain Noninverting Clamp

occur at $2 \times V_H$ and the low clamping level at the output will be $2 \times V_L$. The equations governing the output clamp levels in circuits configured for noninverting gain are:

$$V_{CH} = G \times V_H$$

$$V_{CL} = G \times V_L$$

where: V_{CH} is the high *output* clamping level
V_{CL} is the low *output* clamping level
G is the gain of the amplifier configuration
V_H is the high input clamping level (Pin 8)
V_L is the low input clamping level (Pin 5)

*Amplifier offset is assumed to be zero.

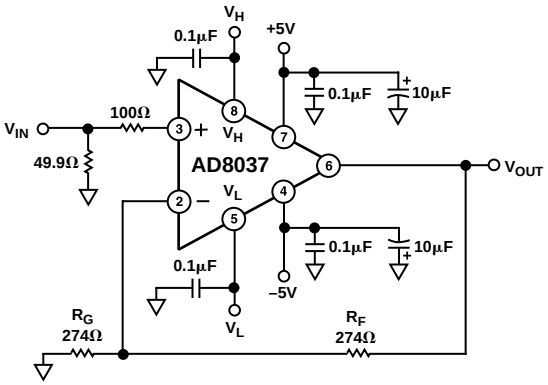

Figure 75. Gain of Two Noninverting Clamp

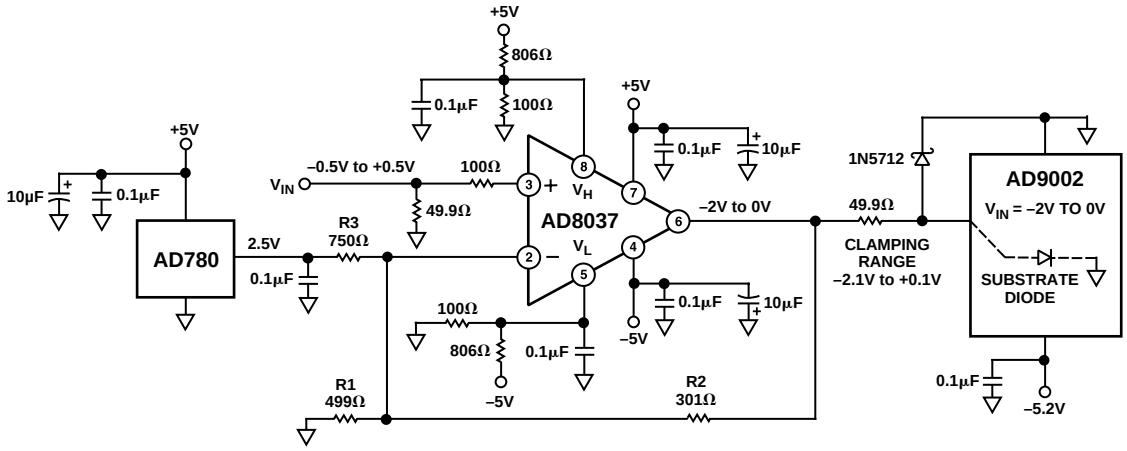

Figure 76. Gain of Two, Noninverting with Offset AD8037 Driving an AD9002—8-Bit, 125 MSPS A/D Converter

Clamping with an Offset

Some op amp circuits are required to operate with an offset voltage. These are generally configured in the inverting mode where the offset voltage can be summed in as one of the inputs. Since AD8036/AD8037 clamping does not function in the inverting mode, it is not possible to clamp with this configuration.

Figure 76 shows a noninverting configuration of an AD8037 that provides clamping and also has an offset. The circuit shows the AD8037 as a driver for an AD9002, an 8-bit, 125 Msps A/D converter and illustrates some of the considerations for using an AD8037 with offset and clamping.

The analog input range of the AD9002 is from ground to –2 V. The input should not go more than 0.5 V outside this range in order to prevent disruptions to the internal workings of the A/D and to avoid drawing excess current. These requirements make the AD8037 a prime candidate for signal conditioning.

When an offset is added to a noninverting op amp circuit, it is fed in through a resistor to the inverting input. The result is that the op amp must now operate at a closed-loop gain greater than unity. For this circuit a gain of two was chosen which allows the use of the AD8037. The feedback resistor, R2, is set at 301 Ω for optimum performance of the AD8037 at a gain of two.

There is an interaction between the offset and the gain, so some calculations must be performed to arrive at the proper values for R1 and R3. For a gain of two the parallel combination of resistors R1 and R3 must be equal to the feedback resistor R2. Thus

$$R1 \times R3/R1 + R3 = R2 = 301\ \Omega$$

The reference used to provide the offset is the AD780 whose output is 2.5 V. This must be divided down to provide the 1 V offset desired. Thus

$$2.5\ V \times R1/(R1 + R3) = 1\ V$$

When the two equations are solved simultaneously we get R1 = 499 Ω and R3 = 750 Ω (using closest 1% resistor values in all cases). This positive 1 V offset at the input translates to a –1 V offset at the output.

The usable input signal swing of the AD9002 is 2 V p-p. This is centered about the –1 V offset making the usable signal range from 0 V to –2 V. It is desirable to clamp the input signal so that it goes no more than 100 mV outside of this range in either direction. Thus, the high clamping level should be set at +0.1 V and the low clamping level should be set at –2.1 V as seen at the input of the AD9002 (output of AD8037).

Because the clamping is done at the input stage of the AD8037, the clamping level as seen at the output is affected by not only the gain of the circuit as previously described, but also by the offset. Thus, in order to obtain the desired clamp levels, V_H must be biased at +0.55 V while V_L must be biased at –0.55 V.

The clamping levels as seen at the output can be calculated by the following:

$$V_{CH} = V_{OFF} + G \times V_H$$

$$V_{CL} = V_{OFF} + G \times V_L$$

Where V_{OFF} is the offset voltage that appears at the output.

The resistors used to generate the voltages for V_H and V_L should be kept to a minimum in order to reduce errors due to clamp bias current. This current is dependent on V_H and V_L (see Figure 61) and will create a voltage drop across whatever resistance is in series with each clamp input. This extra error voltage is multiplied by the closed-loop gain of the amplifier and can be substantial, especially in high closed-loop gain configurations. A 0.1 µF bypass capacitor should be placed between input clamp pins V_H and V_L and ground to ensure stable operation.

The 1N5712 Schottky diode is used for protection from forward biasing the substrate diode in the AD9002 during power-up transients.

Programmable Pulse Generator

The AD8036/AD8037's clamp output can be set accurately and has a well controlled flat level. This along with wide bandwidth and high slew rate make them very well suited for programmable level pulse generators.

Figure 77 is a schematic for a pulse generator that can directly accept TTL generated timing signals for its input and generate pulses at the output up to 24 V p-p with 2500 V/µs slew rate. The output levels can be programmed to anywhere in the range –12 V to +12 V.

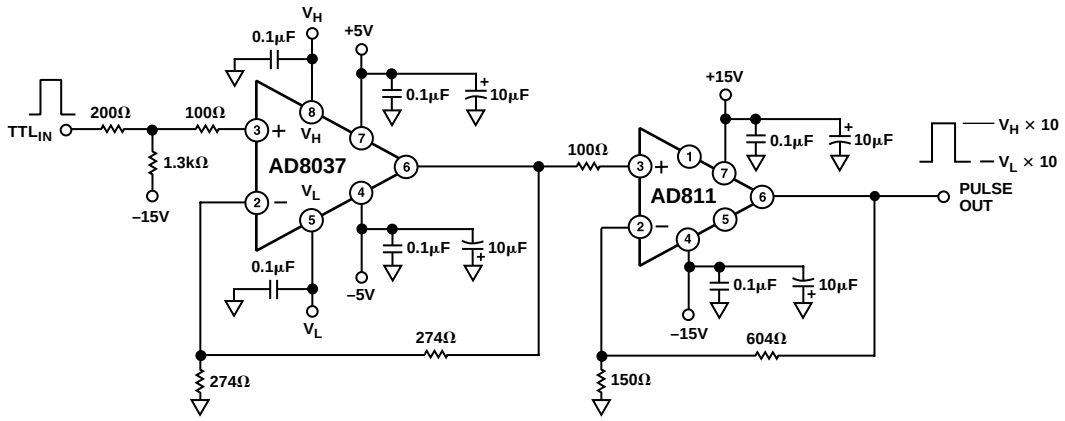

Figure 77. Programmable Pulse Generator

The circuit uses an AD8037 operating at a gain of two with an AD811 to boost the output to the ±12 V range. The AD811 was chosen for its ability to operate with ±15 V supplies and its high slew rate.

R1 and R2 act as a level shifter to make the TTL signal levels be approximately symmetrical above and below ground. This ensures that both the high and low logic levels will be clamped by the AD8037. For well controlled signal levels in the output pulse, the high and low output levels should result from the clamping action of the AD8037 and not be controlled by either the high or low logic levels passing through a linear amplifier. For good rise and fall times at the output pulse, a logic family with high speed edges should be used.

The high logic levels are clamped at two times the voltage at V_H, while the low logic levels are clamped at two times the voltage at V_L. The output of the AD8037 is amplified by the AD811 operating at a gain of 5. The overall gain of 10 will cause the high output level to be 10 times the voltage at V_H, and the low output level to be 10 times the voltage at V_L.

High Speed, Full-Wave Rectifier

The clamping inputs are additional inputs to the input stage of the op amp. As such they have an input bandwidth comparable to the amplifier inputs and lend themselves to some unique functions when they are driven dynamically.

Figure 78 is a schematic for a full-wave rectifier, sometimes called an absolute value generator. It works well up to 20 MHz and can operate at significantly higher frequencies with some degradation in performance. The distortion performance is significantly better than diode based full-wave rectifiers, especially at high frequencies.

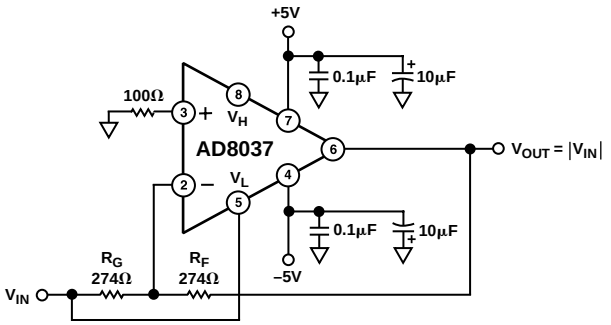

Figure 78. Full-Wave Rectifier

The circuit is configured as an inverting amplifier with a gain of one. The input drives the inverting amplifier and also directly drives V_L, the lower level clamping input. The high level clamping input, V_H, is left floating and plays no role in this circuit.

When the input is negative, the amplifier acts as a regular unity-gain inverting amplifier and outputs a positive signal at the same amplitude as the input with opposite polarity. V_L is driven negative by the input, so it performs no clamping action, because the positive output signal is always higher than the negative level driving V_L.

When the input is positive, the output result is the sum of two separate effects. First, the inverting amplifier multiplies the input by –1 because of its unity-gain inverting configuration. This effectively produces an offset as explained above, but with a dynamic level that is equal to –1 times the input.

Second, although the positive input is grounded (through 100 Ω), the output is clamped at two times the voltage applied to V_L (a positive, dynamic voltage in this case). The factor of two is because the noise gain of the amplifier is two.

The sum of these two actions results in an output that is equal to unity times the input signal for positive input signals, see Figure 79. For a input/output scope photo with an input signal of 20 MHz and amplitude ±1 V, see Figure 80.

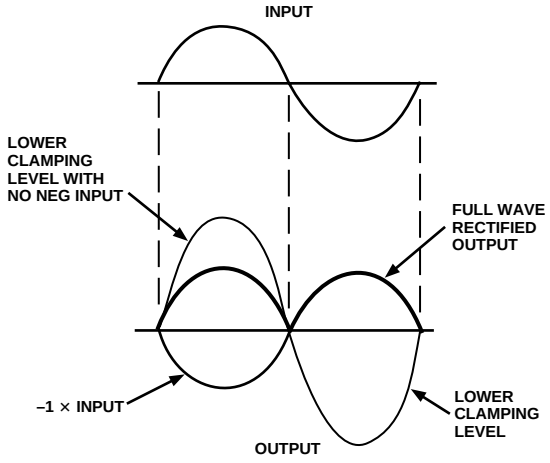

Figure 79.

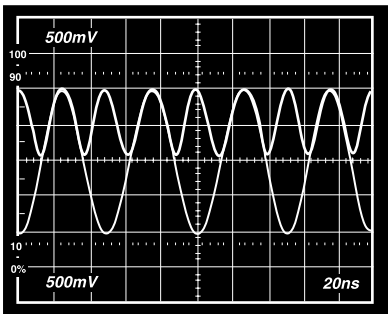

Figure 80. Full-Wave Rectifier Scope

Thus for either positive or negative input signals, the output is unity times the absolute value of the input signal. The circuit can be easily configured to produce the negative absolute value of the input by applying the input to V_H instead of V_L.

The circuit can get to within about 40 mV of ground during the time when the input crosses zero. This voltage is fixed over a wide frequency range and is a result of the switching between the conventional op amp input and the clamp input. But because there are no diodes to rapidly switch from forward to reverse bias, the performance far exceeds that of diode based full wave rectifiers.

The 40 mV offset mentioned can be removed by adding an offset to the circuit. A 27.4 kΩ input resistor to the inverting input will have a gain of 0.01, while changing the gain of the circuit by only 1%. A plus or minus 4 V dc level (depending on the polarity of the rectifier) into this resistor will compensate for the offset.

Full wave rectifiers are useful in many applications including AM signal detection, high frequency ac voltmeters and various arithmetic operations.

Amplitude Modulator

In addition to being able to be configured as an amplitude demodulator (AM detector), the AD8037 can also be configured as an amplitude modulator as shown in Figure 81.

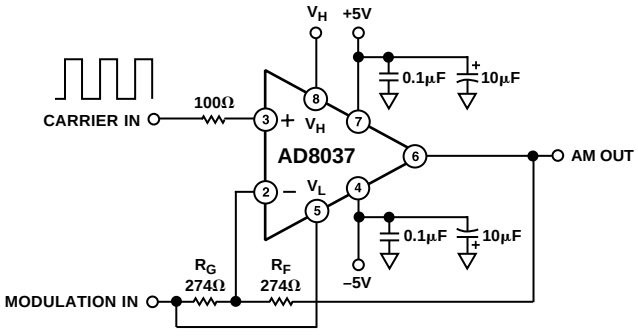

Figure 81. Amplitude Modulator

The positive input of the AD8037 is driven with a square wave of sufficient amplitude to produce clamping action at both the high and low levels. This is the higher frequency carrier signal.

The modulation signal is applied to both the input of a unity gain inverting amplifier and to V_L, the lower clamping input. V_H is biased at +0.5 V dc.

To understand the circuit operation, it is helpful to first consider a simpler circuit. If both V_L and V_H were dc biased at –0.5 V and the carrier and modulation inputs driven as above, the output would be a 2 V p-p square wave at the carrier frequency riding on a waveform at the modulating frequency. The inverting input (modulation signal) is creating a varying offset to the 2 V p-p square wave at the output. Both the high and low levels clamp at twice the input levels on the clamps because the noise gain of the circuit is two.

When V_L is driven by the modulation signal instead of being held at a dc level, a more complicated situation results. The resulting waveform is composed of an upper envelope and a lower envelope with the carrier square wave in between. The upper and lower envelope waveforms are 180° out of phase as in a typical AM waveform.

The upper envelope is produced by the upper clamp level being offset by the waveform applied to the inverting input. This offset is the opposite polarity of the input waveform because of the inverting configuration.

The lower envelope is produced by the sum of two effects. First, it is offset by the waveform applied to the inverting input as in the case of the simplified circuit above. The polarity of this offset is in the same direction as the upper envelope. Second, the output is driven in the opposite direction of the offset at twice the offset voltage by the modulation signal being applied to V_L. This results from the noise gain being equal to two, and since there is no inversion in this connection, it is opposite polarity from the offset.

The result at the output for the lower envelope is the sum of these two effects, which produces the lower envelope of an amplitude modulated waveform. See Figure 82.

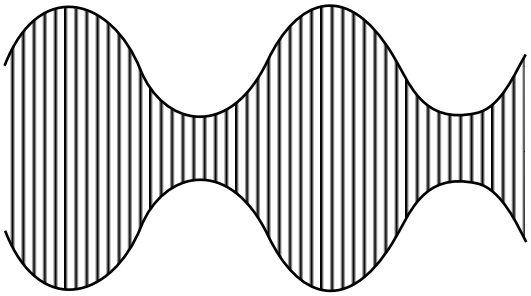

Figure 82. AM Waveform

The depth of modulation can be modified in this circuit by changing the amplitude of the modulation signal. This changes the amplitude of the upper and lower envelope waveforms.

The modulation depth can also be changed by changing the dc bias applied to V_H. In this case the amplitudes of the upper and lower envelope waveforms stay constant, but the spacing between them changes. This alters the ratio of the envelope amplitude to the amplitude of the overall waveform.

Layout Considerations

The specified high speed performance of the AD8036 and AD8037 requires careful attention to board layout and component selection. Proper RF design techniques and low pass parasitic component selection are mandatory.

The PCB should have a ground plane covering all unused portions of the component side of the board to provide a low impedance path. The ground plane should be removed from the area near the input pins to reduce stray capacitance.

Chip capacitors should be used for supply and input clamp bypassing (see Figure 83). One end should be connected to the ground plane and the other within 1/8 inch of each power and clamp pin. An additional large (0.47 μF–10 μF) tantalum electrolytic capacitor should be connected in parallel, though not necessarily so close, to supply current for fast, large signal changes at the output.

The feedback resistor should be located close to the inverting input pin in order to keep the stray capacitance at this node to a minimum. Capacitance variations of less than 1 pF at the inverting input will significantly affect high speed performance.

Stripline design techniques should be used for long signal traces (greater than about 1 inch). These should be designed with a characteristic impedance of 50 Ω or 75 Ω and be properly terminated at each end.

Evaluation Board

An evaluation board for both the AD8036 and AD8037 is available that has been carefully laid out and tested to demonstrate that the specified high speed performance of the device can be realized. For ordering information, please refer to the Ordering Guide.

The layout of the evaluation board can be used as shown or serve as a guide for a board layout.
